#### Outline I

- Testing the Noise Sequence
  - Testing i.i.d Sequence
  - Testing Normality

## Testing the Noise Sequence I

- If there is no dependence among the residuals, then
  - we can regard them as observations of independent random variables,
  - and there is no further modeling to be done except to estimate their mean and variance.
- However, if there is significant dependence among the residuals, then
  - we need to look for a more complex model for the noise that accounts for the dependence.
  - as a result, the past observations of the noise sequence can assist in predicting future values.

### Testing the Noise Sequence II

 Therefore, we examine some simple tests for checking the hypothesis that the residuals are observed values of independent and identically distributed random variables.

## The sample autocorrelation function I

• For large n, the sample auto-correlations of an *i.i.d.* sequence  $X_1, \ldots, X_n$  is defined as

$$\hat{
ho}(h) = rac{\hat{\gamma}(h)}{\hat{\gamma}(0)} ext{ for } -n < h < n,$$

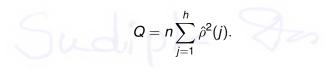

where 
$$\hat{\gamma}(h) = n^{-1} \sum_{t=1}^{n-|h|} (x_{t+h} - \bar{x})(x_t - \bar{x})$$
 and  $\bar{x} = n^{-1} \sum_{t=1}^{n} x_t$ .

## The sample autocorrelation function II

- The auto-correlations of an **i.i.d. sequence**  $X_1, \ldots, X_n$ , with **finite variance** are approximately *i.i.d.* with distribution N(0, 1/n)
- Hence, if  $x_1, \ldots, x_n$  is a realization of such an *i.i.d.* sequence, about 95% of the sample auto-correlations should fall between the bounds  $\pm 1.96/\sqrt{n}$ .

## The portmanteau test I

• Instead of checking to see whether each sample auto-correlation  $\hat{\rho}(j)$  falls inside the bounds defined above, it is also possible to consider the single statistic

• For an **i.i.d. sequence**  $X_1, \ldots, X_n$ , with finite variance Q is approximately distributed as the sum of squares of the independent N(0,1) random variables,  $\sqrt{n}\hat{\rho}(j), j=1,\ldots,h$ , i.e., as chi-squared with h degrees of freedom.

## The portmanteau test II

- A large value of Q suggests that the sample autocorrelations of the data are too large for the data to be a sample from an i.i.d. sequence.
  - We therefore reject the *i.i.d.* hypothesis at level  $\alpha$  if  $Q > \chi^2_{1-\alpha}(h)$ , where  $\chi^2_{1-\alpha}(h)$  is the  $1-\alpha$  quantile of the chi-squared distribution with h degrees of freedom.

# Ljung Box test I

A better and modified estimator

$$Q_{LB} = n(n+2) \sum_{j=1}^{h} \hat{\rho}^2(j)/(n-j).$$

• For an **i.i.d. sequence**  $X_1, \dots, X_n$ , with finite variance Q is approximately distributed as a chi-squared with h degrees of freedom.

# Ljung Box test II

- A large value of Q<sub>LB</sub> suggests that the sample autocorrelations of the data are too large for the data to be a sample from an i.i.d. sequence.
  - We therefore reject the *i.i.d.* hypothesis at level  $\alpha$  if  $Q_{LB} > \chi^2_{1-\alpha}(h)$ , where  $\chi^2_{1-\alpha}(h)$  is the  $1-\alpha$  quantile of the chi-squared distribution with h degrees of freedom.

### The turning point test I

- If  $x_1, \ldots, x_n$  is a sequence of observations, we say that there is a turning point at time i, 1 < i < n,
  - if  $x_{i-1} < x_i$  and  $x_i > x_{i+1}$  or if  $x_{i-1} > x_i$  and  $x_i < x_{i+1}$ .
- If T is the number of turning points of an i.i.d. sequence of length n, then,
  - the probability that a point at time i is a turning point is  $\frac{2}{3}$
  - $\mu_T = E[T] = 2(n-2)/3$

$$\sigma_T^2 = Var[T]$$

$$= (n-2) \left[ \frac{2}{3} - \frac{4}{9} \right] + 2(n-3) \left[ \frac{10}{24} - \frac{4}{9} \right] + 2(n-4) \left[ \frac{54}{120} - \frac{4}{9} \right]$$

$$= (16n - 29)/90$$

### The turning point test II

- A large value of  $T \mu_T$  indicates that the series is fluctuating more rapidly than expected for an *i.i.d.* sequence.
- On the other hand, a value of  $T \mu_T$  much smaller than zero indicates a positive correlation between neighboring observations.

## The turning point test III

- For an *i.i.d.* sequence with n large, it can be shown that T is approximately  $N(\mu_T, \sigma_T^2)$ .
- Therefore, we can carry out a test of the **i.i.d.** hypothesis and reject it at level  $\alpha$  if  $|T \mu_T|/\sigma_T > z_{1-\alpha/2}$ ,
  - where  $z_{1-\alpha/2}$  is the 1  $-\alpha/2$  quantile of the standard normal distribution

## The test for Normality. I

Q-Q Plot: Graphical check for normality Steps:

- Given an *i.i.d.* sequence  $\{x_1, x_2, \dots, x_n\}$  turn it to a standardized form  $\{z_1, z_2, \dots, z_n\}$
- Sort the standardized sequence to  $\{z_{(1)}, z_{(2)}, \dots, z_{(n)}\}$

### The test for Normality. II

• Corresponding to each  $z_{(i)}$  calculate the associated quantile from standard normal  $N_{q_{z_{(i)}}}$ , such that,

$$P\left(Y \leq N_{q_{z_{(i)}}}\right) = \frac{i - 0.5}{n},$$

where  $Y \sim N(0, 1)$ .

- Note: Empirical distribution of Z:  $P(Z \le z_{(i)}) = \frac{\text{Number of points less than equal } z_{(i)}}{\text{Total Points}} = \frac{i}{n}$
- Plot the pair points  $(N_{q_{Z_{(i)}}}, Z_{(i)})$  for  $i = 1, \dots, n$
- If the sequence  $\{x_1, x_2, \dots, x_n\}$  is coming from normal, the plot described above will be straight line passing through origin with slop 1.

## The test for Normality. III

#### Shapiro R<sup>2</sup> test (Shapiro-Francia test)

• Test Statistics, under normality assumption:

$$R^{2} = \frac{\left[\sum_{i=1}^{n} N_{q_{Z_{(i)}}} Z_{(i)}\right]^{2}}{\sum_{i=1}^{n} \left[N_{q_{Z_{(i)}}}\right]^{2} \sum_{i=1}^{n} \left[Z_{(i)}\right]^{2}}$$

- The assumption of normality is rejected if the squared correlation R<sup>2</sup> is sufficiently small
- p values can be found from standard tables
- Decision on Acceptance/Rejection of normality can be made by seeing the p value
